A strategy to get an intuition of the information actually encoded in the weights of a convnet consists of optimizing from scratch a sample to maximize the activation $f$ of a chosen unit, or the sum over an activation map.
Doing so generates images with high frequencies, which tend to activate units a lot. For instance these images maximize the responses of the units “bathtub” and “lipstick” respectively (yes, this is strange, we will come back to it).

Since $f$ is trained in a discriminative manner, a sample $x^*$ maximizing it has no reason to be “realistic”.

We can mitigate this by adding a penalty $h$ corresponding to a “realistic” prior and compute in the end

$$\arg\max_x f(x; w) - h(x)$$

by iterating a standard gradient update:

$$x_{k+1} = x_k - \eta \nabla_{x_k} (h(x_k) - f(x_k; w))$$
A reasonable $h$ penalizes too much energy in the high frequencies by integrating edge amplitude at multiple scales.

This can be formalized as a penalty function $h$ of the form

$$h(x) = \sum_{s \geq 0} \| \delta^s(x) - g \ast \delta^s(x) \|^2$$

where $g$ is a Gaussian kernel, and $\delta$ is a downscale-by-two operator.
\[ h(x) = \sum_{s \geq 0} \| \delta^s(x) - g \ast \delta^s(x) \|^2 \]

We process channels as separate images, and sum across channels in the end.

class MultiScaleEdgeEnergy(nn.Module):
    def __init__(self):
        super().__init__()
        k = torch.exp(-torch.tensor([-2., -1., 0., 1., 2.])**2 / 2)
        k = (k.t() @ k).view(1, 1, 5, 5)
        self.register_buffer('gaussian_5x5', k / k.sum())

    def forward(self, x):
        u = x.view(-1, 1, x.size(2), x.size(3))
        result = 0.0
        while min(u.size(2), u.size(3)) > 5:
            blurry = F.conv2d(u, self.gaussian_5x5, padding = 2)
            result += (u - blurry).view(u.size(0), -1).pow(2).sum(1)
            u = F.avg_pool2d(u, kernel_size = 2, padding = 1)
        result = result.view(x.size(0), -1).sum(1)
        return result

Then, the optimization of the image \textit{per se} is straightforward:

```python
model = models.vgg16(pretrained=True)
model.eval()
edge_energy = MultiScaleEdgeEnergy()
input = torch.empty(1, 3, 224, 224).normal_(0, 0.01)
input.requires_grad_()
optimizer = optim.Adam([input], lr = 1e-1)

for k in range(250):
    output = model(input)
    score = edge_energy(input) - output[0, 700] # paper towel
    optimizer.zero_grad()
    score.backward()
    optimizer.step()

result = 0.5 + 0.1 * (input - input.mean()) / input.std()
torchvision.utils.save_image(result, 'dream-course-example.png')
```

(take a second to think about the beauty of autograd)
VGG16, maximizing a channel of the 4th convolution layer

VGG16, maximizing a channel of the 7th convolution layer
VGG16, maximizing a unit of the 10th convolution layer

VGG16, maximizing a unit of the 13th (and last) convolution layer
VGG16, maximizing a unit of the output layer

“Box turtle”

“Whiptail lizard”

VGG16, maximizing a unit of the output layer

“African chameleon”

“Wolf spider”
VGG16, maximizing a unit of the output layer

“King crab”  “Samoyed” (that’s a fluffy dog)

VGG16, maximizing a unit of the output layer

“Hourglass”  “Paper towel”
VGG16, maximizing a unit of the output layer

“Ping-pong ball”    “Steel arch bridge”

VGG16, maximizing a unit of the output layer

“Sunglass”    “Geyser”
These results show that the parameters of a network trained for classification carry enough information to generate identifiable large-scale structures.

**Although the training is discriminative, the resulting model has strong generative capabilities.**

It also gives an intuition of the accuracy and shortcomings of the resulting global compositional model.

---

**Adversarial examples**
In spite of their good predictive capabilities, deep neural networks are quite sensitive to adversarial inputs, that is to inputs crafted to make them behave incorrectly (Szegedy et al., 2014).

The simplest strategy to exhibit such behavior is to optimize the input to maximize the loss.

Let $x$ be an image, $y$ its proper label, $f(x; w)$ the network’s prediction, and $\mathcal{L}$ the cross-entropy loss. We can construct an adversarial example by maximizing the loss. To do so, we iterate a “gradient ascent” step:

$$x_{k+1} = x_k + \eta \nabla_x \mathcal{L}(f(x_k; w), y).$$

After a few iterations, this procedure will reach a sample $\tilde{x}$ whose class is not $y$.

The counter-intuitive result is that the resulting miss-classified images are indistinguishable from the original ones to a human eye.
model = torchvision.models.alexnet(pretrained = True)
target = model(input).argmax(1).view(-1)
cross_entropy = nn.CrossEntropyLoss()
optimizer = optim.SGD([input], lr = 1e-1)
nb_steps = 15
for k in range(nb_steps):
    output = model(input)
    loss = - cross_entropy(output, target)
    optimizer.zero_grad()
    loss.backward()
    optimizer.step()
Another counter-intuitive result is that if we sample 1,000 images on the sphere centered on $x$ of radius $2\|x - \tilde{x}\|$, we do not observe any change of label.
